    The growth of a semi-permeable membrane uses a reaction chamber (1) and a
    medium chamber (2) through which a gas phase and a liquid nutritional
    phase flow. They pass over a semi-permeable membrane (M1) which serves as
    the substrate for the new membrane. The novelty is that the new cell
    material is inoculated to the semi-permeable membrane to form a first
    layer. The lower side of the semi-permeable membrane is
     flushed by nutritional solution and the upper side is flushed by
     the gas phase. Controlled cell growth ensues to form a number of layers
     and a cell structure (ML) from which metabolic by-products are removed by
     the gas and liquid phases to produce a cell structure which can be removed
     under sterile conditions for further use.
          USE- The process and assembly produce a semi-permeable membrane of
     defined geometry, as used in the stations associated with human organ
```

ADVANTAGE - The process and assembly are suitable for automated operation, thus largely removing the requirement for manual intervention. Dwg.1/3

transplantation.
